## **Executive summary**

Singapore is facing an unprecedented health crisis, with a rapidly ageing population surging from 11.1% elderly to 18.4% over the past 10 years, further projected to increase to 25% in 2030 (Fang, 2022). Furthermore, increasingly more people suffer from lifestyle-related diseases from having a sedentary lifestyle (Lai, 2021), such as cardiovascular diseases, the second leading cause of death in Singapore amounting to nearly 1 in 3 deaths in 2018 (AIA, 2019). National Heart Centre Singapore (NHCS) already oversees hundreds of thousands of patients each year for cardiovascular diseases, and patient numbers are projected to further increase over the following years. The healthcare sector in Singapore shoulders an immense, growing burden that may eventually overwhelm our healthcare services.

To alleviate the stress on NHCS, we aim to make use of Artificial Intelligence (AI) and Machine Learning (ML) via predictive analysis for accurate and early detection of heart diseases. This allows NHCS to detect patients at a higher risk of heart disease, with the help of predictive analysis, and provide them with timely treatment. We also seek to reduce the resources needed for heart disease screening by providing a novel way of predicting heart disease based on non-medical data.

Currently, healthcare diagnostics tests are time consuming and expensive, often unaffordable to many patients. Furthermore, current AI models have high false negative rates where heart diseases go undetected.

Hence, this report aims to employ a model which effectively targets the above problem statements.

Firstly, we explored the different variables from the dataset via exploratory analysis. to examine their relation to heart disease and within the predictors. The emphasis is on how non-medical factors can influence heart disease, allowing us to extend these insights to patients subsequently help them reduce their likelihood of heart disease by correcting unhealthy habits.

Secondly, we applied five different models: Logistic Regression, Classification And Regression Tree (CART), Gradient Boosting Machine (GBM), Support Vector Machine (SVM) and Neural network. By comparing these models, we decided on the most accurate model in detecting the presence of heart disease.

Thirdly, the final model: Logistic regression model will be implemented into the app to allow patients to self-check their risk of heart disease through data available to them without needing advanced cardiac diagnostic tests or expert opinions from healthcare professionals. By accessing their risk of heart disease, individuals will be recommended on subsequent steps of action such as an appointment with the doctor.

Overall, this helps target our problem statement of time consuming and expensive tests using non-medical data to allow patients to gauge their risk prior and decide on their next course of action. With our model's high recall score, we also avoid giving high risk individuals a false sense of safety.

This will overcome the potential business problems as the app is easily accessible and cost effective. The comprehensive nature of the app allows individuals to make well informed decisions on whether it is necessary to consult a cardiologist based on the results of the diagnostic test taken through the app.

## **1. Problem Statement**

### **1.1 Introduction to problem statement**

Despite having advanced healthcare procedures in place to diagnose heart diseases, there are still limitations faced as stated below.

#### **Time-Consuming Diagnostic Tests**

Currently, NHCS uses a series of complex cardiac diagnostic tests in the diagnosing of heart diseases. These tests are time-consuming. For instance, the Ambulatory Electrocardiogram requires the patient to be monitored for 24-48 hours (Lau, 2019). However, nearly 50% of potentially salvageable heart muscle is lost within an hour of the coronary artery being blocked. Given, the time sensitivity of the test results, many patients could have succumbed to life-threatening episodes of heart attacks and other symptoms while waiting for the test results. Only 26% of 500 heart attack survivors managed to get treatment in time (SBS News, 2016).

#### **High Cost of Tests**

These diagnostic tests are also highly expensive (Table 1.1), potentially deterring high-risk patients from taking health screenings or seeking treatment for their conditions – the delay in early treatment of heart disease, would, besides worsening health outcomes for patients, exacerbate the strain on our healthcare sector as the treatment required would demand more attention and medical resources.

Consultation	Electrocardiogram	Echocardiogram	Treadmill Test
\$180-\$300	\$60-\$80	\$450-\$600	\$350-\$500

*Table 1.1. Cardiac Diagnostic Test Costs in Singapore* (Macdonald, 2022)

#### **Manpower Shortage**

Manpower, a critical resource for Singapore's healthcare system, is diverted away to conduct these time-consuming tests. This is especially pressing as there is an existing workforce shortage in Singapore's healthcare sector, to which the government has desperately responded by increasing reliance on foreign workers, subsidising salary increases, and rolling out staff support and wellness programmes (RSM, 2021). These approaches, while beneficial to the employees, are draining resources from both the government and the hospitals which can be better utilised.

#### **Scant Medical Records**

Cardiac patients are initially assessed based on their medical history, as well as that of their families. Therefore, the validity of the diagnosis relies heavily on the availability and accuracy of these records, which may not always be complete and available for medical practitioners.

### **1.2 Reasons**

#### **1.2.1 Incompleteness of current early detection models**

Currently, there exist multiple models that predict heart disease based on medical data. However, beyond medical data, behavioural and psychological factors could also affect the risk of heart disease. There is tremendous, untapped potential in using these factors for more robust and powerful analytics than simply using medical data.

A study examined 4 conventional heart disease prediction approaches and found that the accuracy of the models ranged from a high of 85% to 95% (Table 2.1).

**Table 1**

Comparative analysis of different machine learning methods.

Methods	Accuracy	Precision	Recall	F1-measure
Naïve Bayes weighted approach	86.00	82.34	87.25	89.21
2 SVM's and XGBoost	94.03	86.56	94.78	92.79
SVM and DO	89.4	66.1	81.3	82.1
XGBoost	95.9	97.1	94.67	95.35

*Table 2.1. Analysis of the 4 heart disease detection models (Nagavelli, et al., 2022)*

Despite the deceptively high accuracy, these models had a concerning false negative rate of 40-45% for all 4 models. False negatives are especially dangerous as this means 40% of cases of heart disease go undetected, and consequently, untreated. Therefore, another priority of our model is to minimize the false negative rate in prediction of heart disease.

Naïve Bayes and weighted approach	2 SVM's and XGBoost	SVM and DO	XGBoost
44.5%	47.5%	43.4%	45.7%

*Table 2.2. A false negative rate of 4 heart disease detection models (Nagavelli, et al., 2022)*

### 1.2.2 Usefulness of non-medical factors in early detection models

The World Health Organisation states that the key behavioural factors of cardiovascular diseases are the use of tobacco, lack of physical activity and consumption of unhealthy food. (WHO, 2021). The usefulness of behavioural factors can also be seen by a quantised study that was conducted over 6 months at the diabetes units of health centres in Iran. The study showed that 9 modifiable risk factors such as smoking and consumption of fruits and vegetables were associated with more than 90% of the risk of a heart attack in this large global case-control study in 52 countries (Sabzmakan, et al., 2014). Furthermore, even physiological factors have been shown to be correlated with heart disease. Depression for instance, is associated with a 3-fold increase in the risk of heart disease. When Coronary Heart Disease (CHD) risk estimates were combined across studies, depression was associated with a significantly increased risk of CHD with a combined risk ratio (RR) of 1.64 (95% confidence interval [CI]=1.29-2.08,  $P<.001$ ), with significant heterogeneity between studies. Hence, this highlights the importance of behavioural factors given their correlation to heart disease (Smith et al., 2011).

### 1.2.3 Current models' reliance on complex medical data

Most modern heart disease early detection models require complex medical data, which in turn requires extensive medical tests to be conducted prior. This may not be well-received, especially by the elderly. Additionally, people who have not done all these medical tests will not have the data required for conventional prediction models to predict, so they won't be able to receive an early diagnosis until they undergo the expensive and resource-draining cardiac diagnostic tests.

## **2. Project Objectives**

We would like to build a model that predicts the probability of heart disease based on non-medical data which are easily accessible by everyone, such as daily vegetable intake, age, mental well-being and more, so that a heart disease diagnosis can be quickly generated anytime, anywhere, by anybody.

## **3. Data and Methodology**

### **3.1 Data Sourcing**

We aim to construct a model that predicts likelihood of CHD based on behaviour and demographics. To construct a complete and accurate model, we need to consider a wide range of behavioural & demographic factors that affect risk of CHD.

The Behavioural Risk Factor Surveillance System (BRFSS) conducted public health surveys through the telephone, collecting objective state data of U.S. citizens based on their behaviour which might result in chronic health problems in the long run. (CDC<sup>1</sup>, 2022) The data comes from an official source, and contains an extensive collection of non-medical factors that could potentially contribute towards risk of CHD.

To better suit this dataset for Singapore use, we avoided taking U.S. specific variables like state of residence, whether the person has served in US armed forces, and housing types. Instead, we focused on more general factors that apply cross-borders.

### **3.2 Data Cleaning**

BRFSS has provided a comprehensive dataset with 441,456 rows and 330 columns, but some columns are duplicated and unrelated, such as interview date & country of residence. Furthermore, the dataset is too large to perform data exploration and data modelling. Therefore, we put the dataset through a sequence of dimensionality reduction and cleaning procedures in our data processing pipeline, extracting only the useful information.

#### **3.2.1 Recoding values**

We start by correcting the encodings used by the survey. Based on the codebook, columns like [MENTHLTH](#) use the encodings: 88 for “None”, 77 for “Don’t Know/Not Sure”, and 99 for “refused”. Left untreated, our models will misinterpret these values. Therefore, these structural errors need to be fixed by recoding values as 0 for “None”, NA for “Don’t Know/Not Sure” and “Refused”.

The sequence of questions also matters. For instance, if the respondent has previously responded to [ALCDAY5](#) with 888<sup>2</sup>, then [AVEDRNK](#) would not be asked, but will be recorded as NA. This explains why questions further down the survey have more missing values. In fact, [AVEDRNK2](#) has 52.2% NA values. To fix this column, we recorded a 0 in [AVEDRNK2](#) where [ALCDAY5](#) == 888, reducing NA values to 5.82%. Same applies for [SCNTWRK1](#).

#### **3.2.2 Removing duplicates**

The dataset had no duplicate rows.

### 3.2.3 Extracting relevant columns

We extracted a subset of the data frame to include non-medical factors. Behavioural factors like total number of alcoholic drinks consumed per week and demographic factors like weight were chosen. Unrelated columns like date month and state were filtered out.

### 3.2.4 Creating the response variable

We dropped `CVDCRHD4` since it was found to be a subset of `MICHD`. `MICHD` was renamed to “Y”.

### 3.2.5 Correcting numeric values

According to the codebook, `WTKG3`, `BMI5`, `GRENDAY`, `FRUITDA1` and `BEANDAY` in the dataset have an implied 2 decimal points. Thus, we divide the values in these columns by 100.

### 3.2.6 Correcting data types

`PA1MIN`, `PA1VIGM`, `SCNTWRK1`, `CHILDREN` are set as integers.

`SEX`, `HLTHPLN1`, `MEDCOST`, `ADDEPEV2`, `MARITAL`, `EMPLOY1`, `INCOME2`, `INTERNET` are set as categorical variables.

`SMOKER3`, `CHECKUP1`, `SEATBELT`, `EDUCA`, `AGEG5YR` are set to ordinal variables.

### 3.2.7 Remove rows with missing response variable

In supervised learning, all the response variables must be available for testing and training. Hence, we filtered out the rows where Y is missing since they are unusable.

### 3.2.8 Removed rows with missing values in columns where more than 20% data are missing

Some of the critical columns have high percentages of missing data. To ensure the usability of these columns while preserving the truthfulness of the data, we chose to drop all rows where data is missing in the columns with more than 20% missing values (`SCNTWRK1`, `PA1VIGM`, `PA1MIN`) as opposed to resorting to imputation which introduces error and biases into our data. With 441,456 records to work with, these errant rows could be removed without causing data insufficiency.

### 3.2.9 Removed rows with less than 80% of that rows' columns filled [only keep rows that have less than 20% NA value]

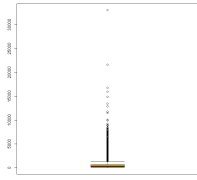

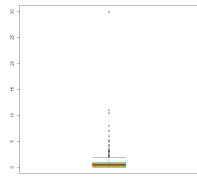

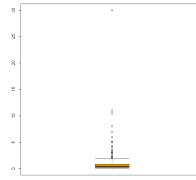

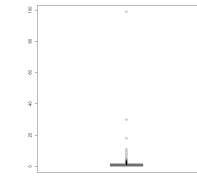

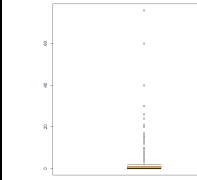

Given the large number of rows, we can further reduce the dimensionality and still have sufficient data for modelling. Hence, to ensure even greater accuracy in the models like regression, through the predominant usage of actual over imputed values, we removed rows with more than 20% missing values.

### 3.2.10 Balancing the dataset

Naturally, the dataset is highly imbalanced with a 1:9 proportion (heart disease: no heart disease). With imbalanced data, the model will develop a bias towards predicting the majority class, which is the case of no heart disease (Brownlee, 2020). This gives rise to a higher false negative rate which is a serious error as high-risk patients will be predicted to have no heart disease which could be fatal if ignored. Hence, we need to balance the data 1:1 through under sampling to reduce false negative rates.

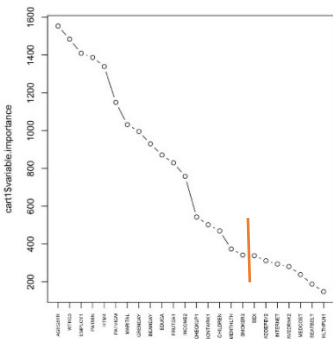

### 3.2.11 Removal of outliers

Through examination of statistical summary and boxplots, certain columns: **PA1MIN**, **GRENDAY**, **BEANDAY**, **FRUTDA** and **AVEDRNK2** have extreme or unreasonable values. Hence it is important to remove the outliers to make the data less skewed especially as outliers can drastically distort or change the fit estimates and predictions (Prabhakaran, 2017).

				
<p><b>PA1MIN:</b> Minutes of total Physical Activity per week.</p> <p>PA1MIN has extreme and unreasonable outliers. For example, the maximum value of PA1MIN is 33080 minutes (551 hours). There are many anomalous data points as such which exceed maximum hours in a week. These outliers must be removed.</p>	<p><b>GRENDAY:</b> Dark green vegetable intake in times per day</p> <p>GRENDAY has extreme outliers too. Maximum green vegetables intake is 30 times a day. These extreme outliers will be removed.</p>	<p><b>BEANDAY:</b> Bean intake in times per day</p> <p>BEANDAY has extreme outliers as well. The maximum value of BEANDAY for instance, which is very distant from the other points, so these outliers will be removed.</p>	<p><b>FRUTDA1:</b> Fruit intake in times per day</p> <p>FRUTDA1 has unreasonable outliers too. For example, the maximum value of FRUTDA1 is 99. It is impossible for someone to consume fruits 99 times per day.</p> <p>This is unreasonable and thus outliers in FRUTDA1 were removed.</p>	<p><b>AVEDRNK2:</b> Total number of drinks per day</p> <p>AVEDRNK2 has a max value of 72 drinks a day, way beyond the life-threatening limit. Thus, outliers were removed from AVEDRNK2 as well.</p>

### 3.2.12 Using CART model to further reduce dimensionality through variable importance

The dataset set still has too many columns (27 columns) to perform modelling. Hence using a CART model, we further filtered the vital columns by variable importance.

	<p>Through the plot, we decided to cut off between <b>SMOKER</b> and <b>SEX</b> to reduce dimensionality of the dataset by 30% for modelling. Hence utilising this as the cut-off point, the variables lesser than this threshold is removed from the dataframe.</p>
---	--

### 3.2.13 Data imputation

After removal of rows, the remaining missing values are imputed using the K-Nearest Neighbour method (KNN).

KNN is our imputation method of choice as it allows for imputation of both numerical and categorical variables. KNN imputation can also be done in the presence of other missing values by utilizing alternative columns to compute distances, making it more robust than imputation via regression models.

KNN is a distance-based algorithm that typically uses Euclidean distance to compute closeness of different rows. However, we did not normalize the values because KNN from the VIM package uses Gower distance instead, where numeric variables are range normalized.

### 3.2.14 End of data cleaning

The final dataset had a shape of (21214, 18).

Finalized columns: WTKG3, HTM4, AGE5YR, EMPLOY1, GRENDAY, FRUTDA1, MARITAL, BEANDAY, EDUCA, INCOME2, PA1MIN, PA1VIGM, CHECKUP1, MENTHLTH, SCNTWRK1, CHILDREN, SMOKER3, Y

## 3.3 Data Exploration

### 3.3.1 Bivariate analysis

We used the correlation matrix to examine linear correlations between pairs of variables.

## Continuous variables

### NUTRITION VS HEART DISEASE

#### BEANS INTAKE

From the graph, the predominant trend is that the lower the bean intake, the greater the risk of heart disease. As beans intake increases beyond 0.3, there is a lower risk of heart disease.

#### FRUITS INTAKE

From the graph, the predominant trend is that the lower the fruit intake, the greater the risk of heart disease. As fruit intake increases beyond 0.4, there is a lower risk of heart disease.

#### VEG. INTAKE

From the graph, the predominant trend is that the lower the vegetable intake, the greater the risk of heart disease. As vegetable intake increases beyond 0.45, there is a lower risk of heart disease.

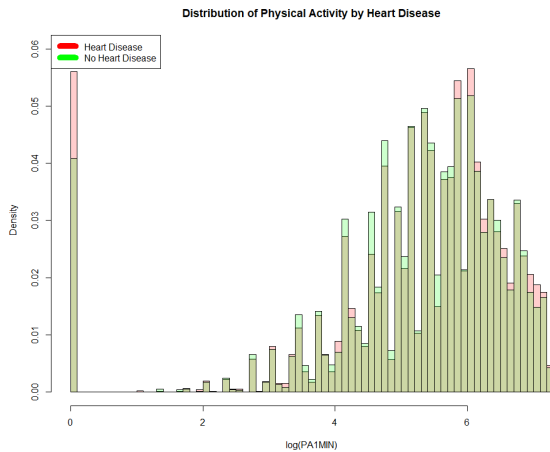

### OVERALL NUTRITION INTAKE

The graph shows a linear combination of all three variables: GRENDAY, FRUTDA1, BEANDAY against the response variable, MICHHD. As the nutrition intake increases beyond 1.4 times, there is a lower risk of heart disease. This is synchronous to research which shows that an increase in the consumption of vegetables or fruits by a serving reduces the risk of heart disease by 4%. (K J et.al, n.d.) Similarly, consumption of beans reduces blood cholesterol, a leading cause of heart disease. (American Heart Association, 2018).

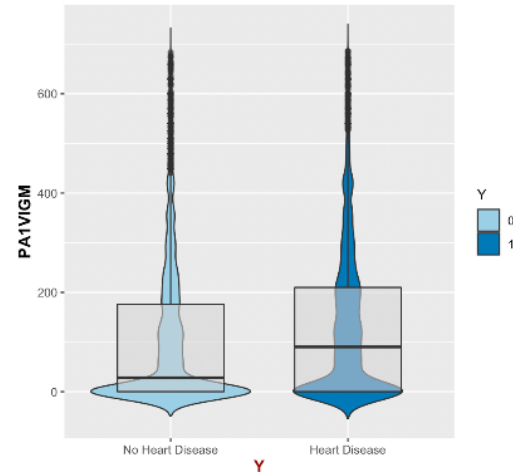

## PHYSICAL FITNESS VS HEART DISEASE

### NORMAL PHYSICAL ACTIVITY

We observe that the longer the duration of physical activity, the lower the risk of heart disease. This is in line with the research which shows that adults who had 150 to 300 minutes of physical activity had a 63% lower risk of having heart disease. (American Heart Association, 2022)

### INTENSE PHYSICAL ACTIVITY

By comparing the plots, it is observed that the more intense the physical activity is, the higher the risk of heart disease. This is synchronous with the research which shows that intensive exercise may increase the risk of getting cardiac arrest. (Healthessentials, 2020)

## BODY MEASUREMENTS VS HEART DISEASE

### WEIGHT

The graph shows that the heavier an individual, the higher the risk of heart disease. This is synchronous with research which highlights that excess weight can lead to fatty material building up in your arteries which increases risk of heart disease (BHF, n.d.). This can be especially seen when weight increases beyond 70kg. This is accompanied by a higher risk of heart disease.

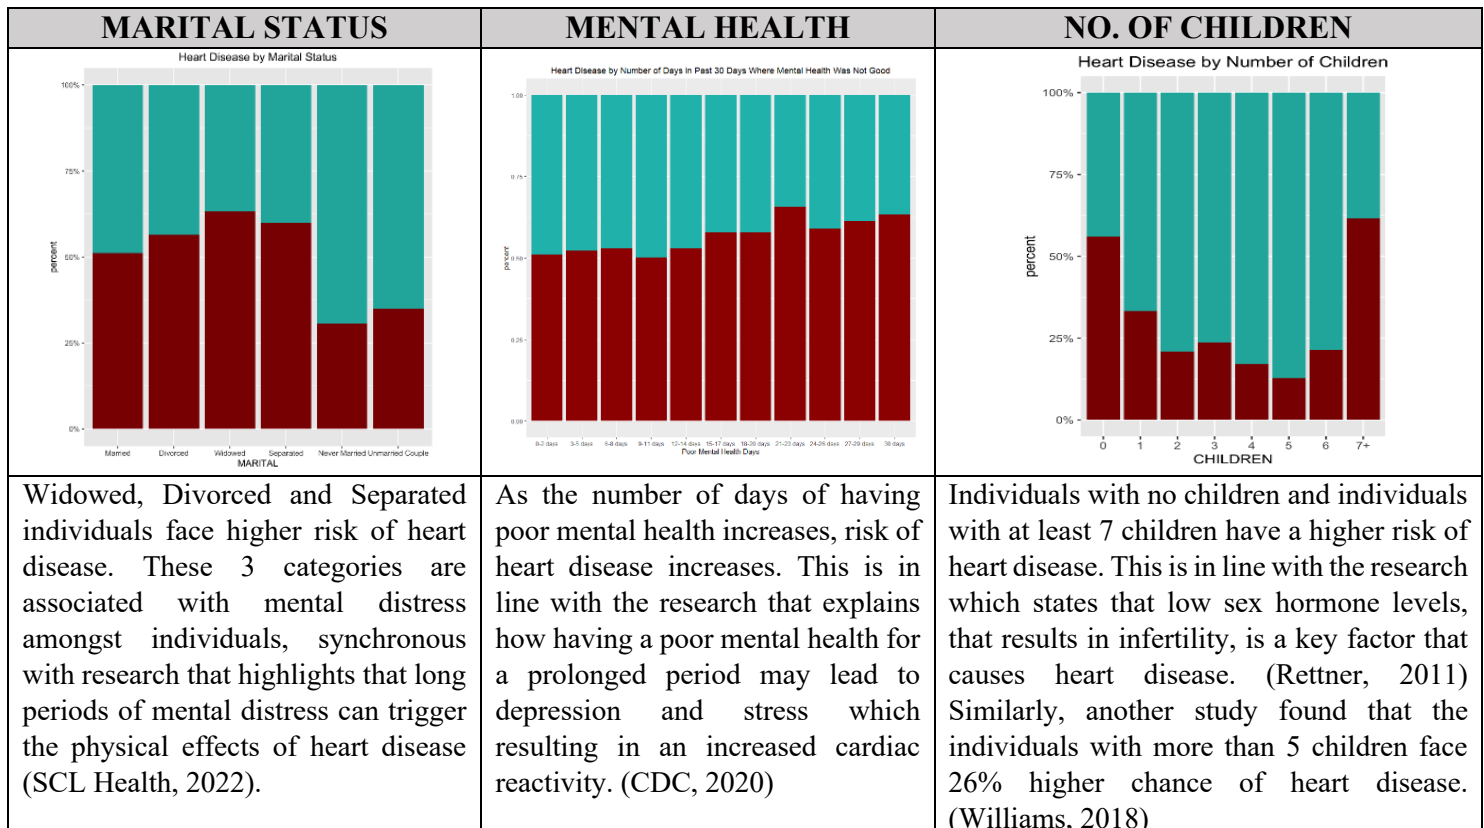

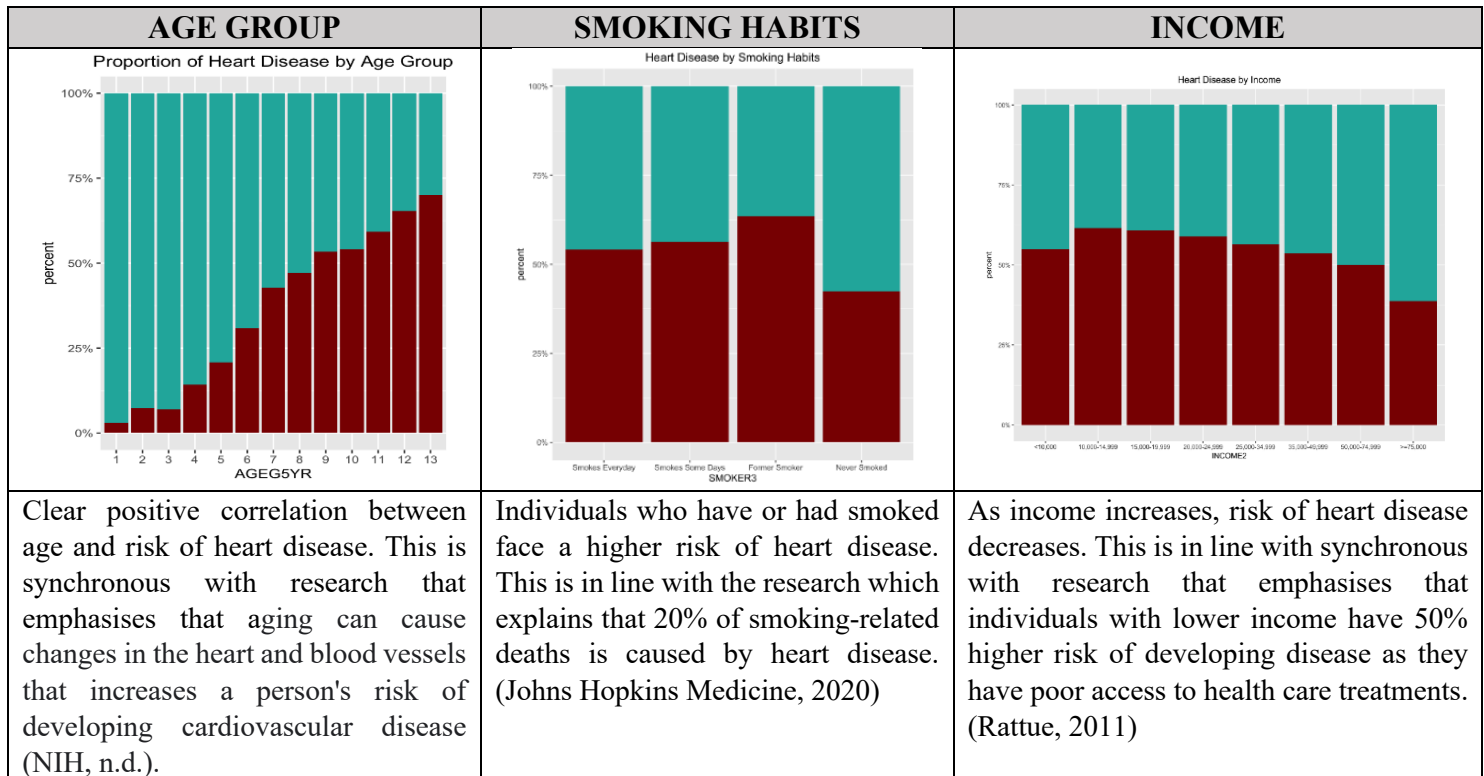

### BMI

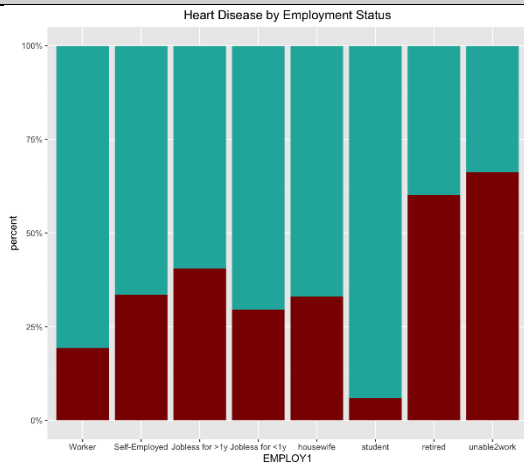

The graph shows that as BMI increases, the higher the risk of heart disease. This is synchronous with research which highlights the danger of crossing the healthy range of BMI as it increases the chance of contracting heart diseases (John Hopkins, n.d.). This can be especially seen when BMI increases beyond 30. This is accompanied by a higher risk of heart disease.

## Categorical Variables

Y  
 No Heart Disease  
 Heart Disease

## EMPLOYMENT STATUS

Unemployed individuals are at a higher risk of heart disease. This is most prominent in retired and unable-to-work individuals which could be largely attributed to age. However, the jobless individuals also have a greater likelihood of getting heart disease. This is synchronous with research as a study showed that unemployment and loss of jobs may increase the risk of heart attack (Mann, 2012).

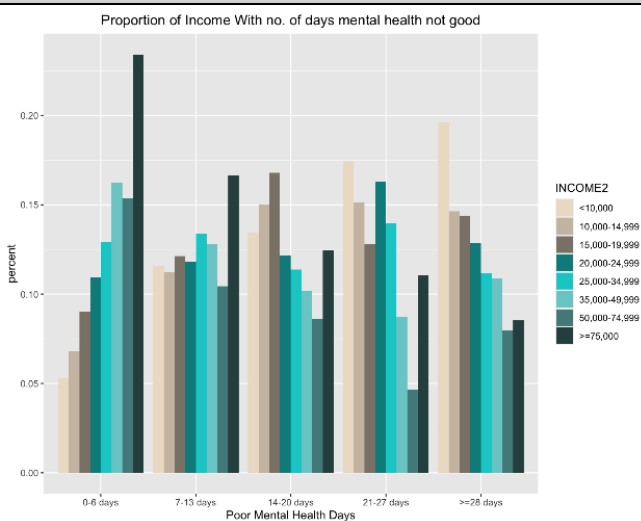

## EDUCATION

The more educated an individual is, the lower the risk of heart disease. This is synchronous with the research that emphasises that with higher level of education, individuals are more likely to get better jobs which would enable them to get health insurance and thus seek a better treatment. Males with grade school level education were 17% more likely to have heart disease compared to males with graduate school education. (Merschel, 2020)

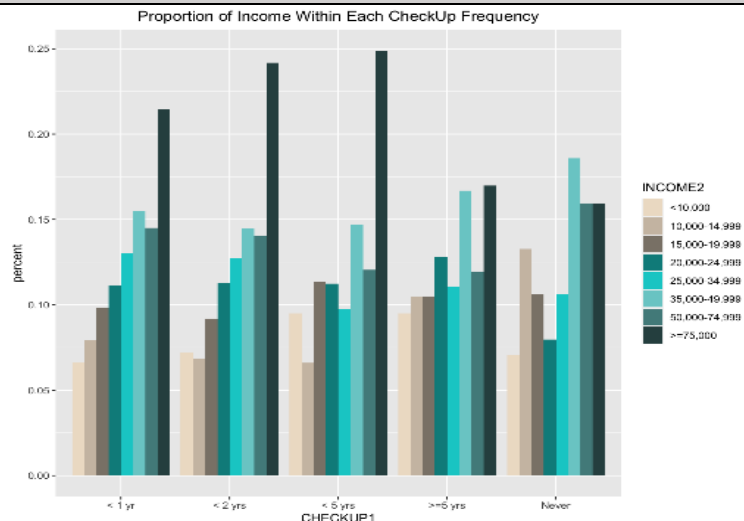

## BIVARIATE ANALYSIS BETWEEN 2 PREDICTOR VARIABLES

### INCOME VS MENTAL HEALTH

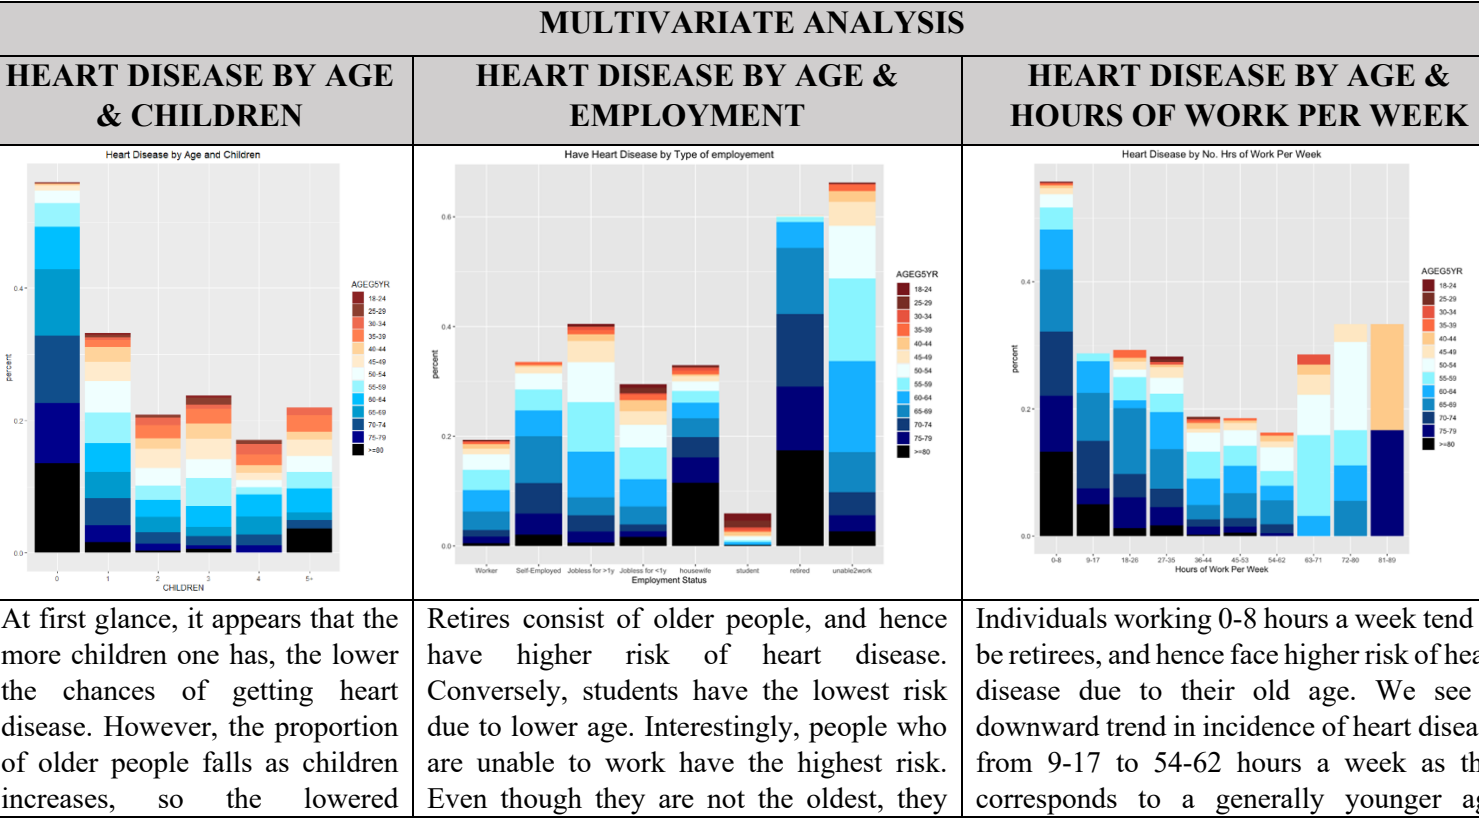

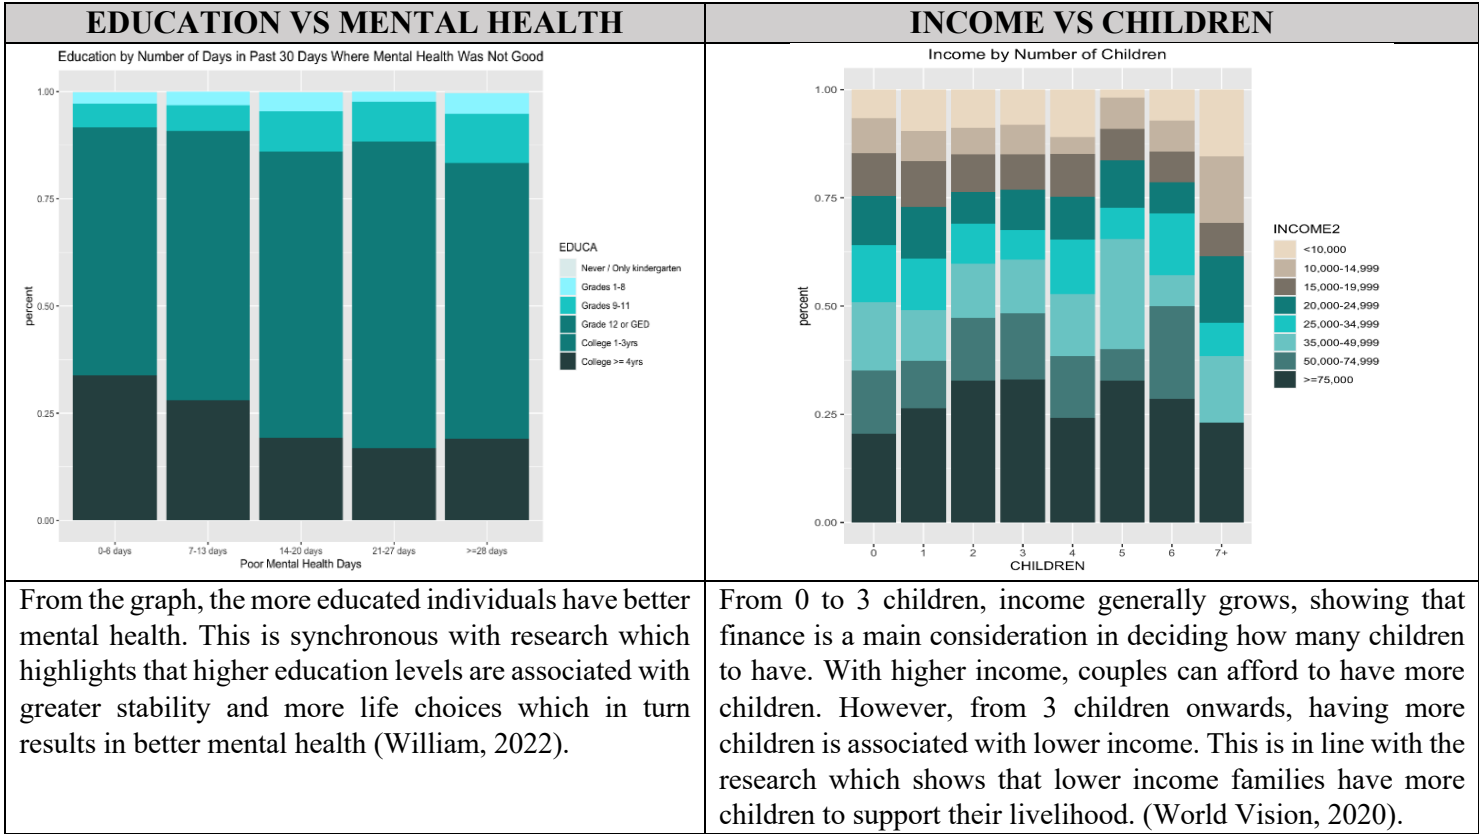

Individuals with higher income tend to have better mental health. This is synchronous with the research which explains that individuals with lower income have higher suicide rate as one of the main concerns is to meet the basic needs. (Sareen et.al, 2011)

### INCOME VS CHECKUP FREQUENCY

From the graph, it can be observed that individuals with higher income go for a routine check-up compared to individuals with a lower income. This is in line with the research that states how higher income individuals have greater affordability to access qualified hospitals and thus allowing them to go for routine medical check-ups. (Shin et.al, 2018)

incidence of heart disease could actually be a result of lower ages. Nonetheless, having children can reduce loneliness and even bring fulfilment, thereby improving mental health and lowering heart disease risk.	face a greater health risk due to pre-existing, crippling health conditions that may pose as risk factors for heart disease, such as severe mental illnesses and extreme obesity.	distribution. The minimum point is at 54-62 hrs of work / week, corresponding to a typical 9 hour, 5/6 day work week. Beyond this level, heart disease risk increases. Even if people in these categories are younger, the effects of overworking triumphs, drastically increasing risk of heart diseases (Sunrise Hospital and Medical Center, 2020).
---	---	--

# 4. Modelling

## 4.1 Overall approach

We utilized 5 different models to predict heart disease, and derived the best model based on context-specific metrics.

## 4.2 Pre-processing

Feature scaling was first conducted to normalize the numeric variables to between 0-1 since the variables have highly varying magnitudes. PA1MIN for instance, ranges from 0 to 1300+, whereas MENTHLTH ranges only from 0-30. Without feature scaling, distance-based models like SVM may be biased towards features with higher magnitudes (Bhandari, 2020).

Feature scaling also smoothens the gradient descent process, especially for Neural Network and SVM, helping the models converge quicker (Raj, n.d.).

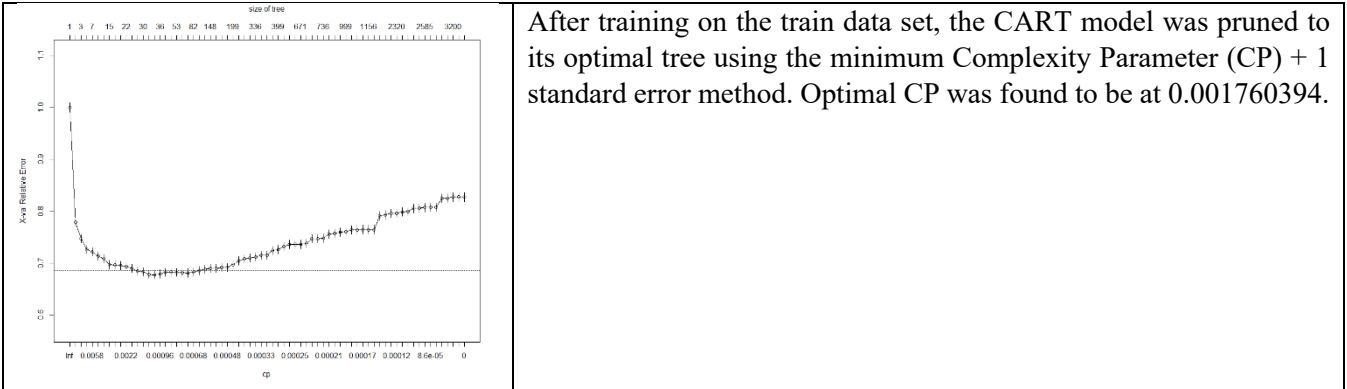

## 4.3 Training

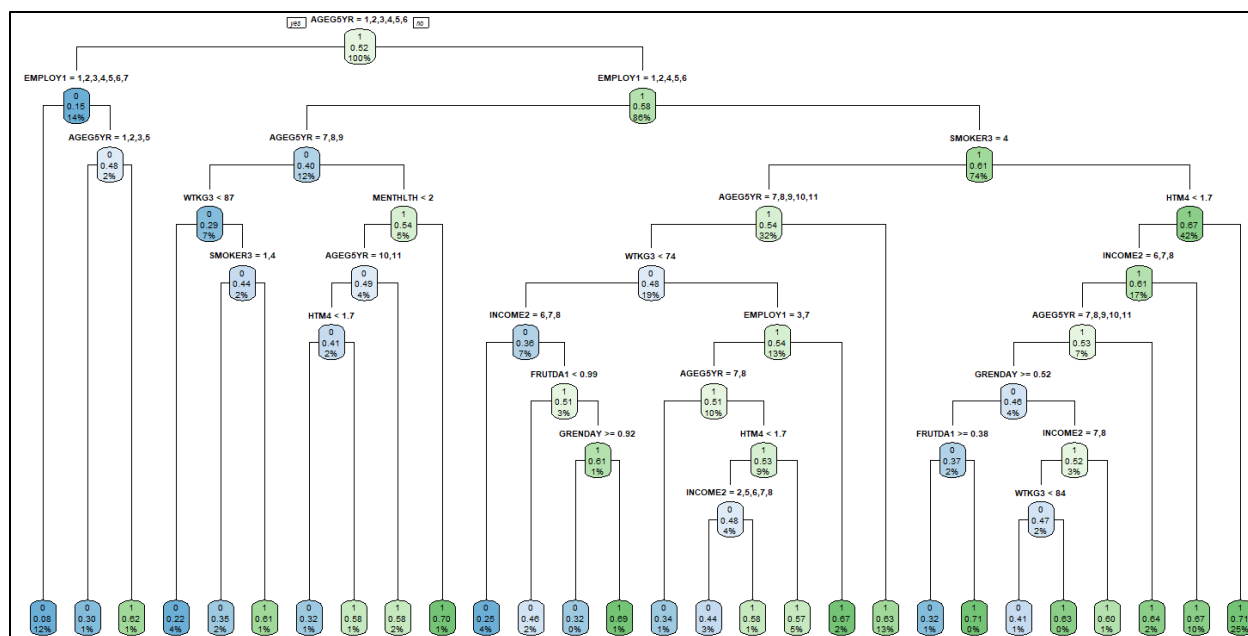

Since decision trees and ensemble methods like CART and GBM are not sensitive to variance in data (Thenraj, 2020), the non-scaled dataset is used for these models, whereas the scaled dataset is used for logistic regression, neural network and SVM. All 5 models were trained using a 70-30 train test split.

## 4.4 Models

### 4.4.1 CART

CART is a binary tree, where each split is based on the values of a predictor variable. The best splits are calculated based on the splitting criteria of minimizing Gini Impurity.

#### 4.4.2 GBM

Gradient boosting is an ensemble method where outputs from individual trees are combined. Weak learners are combined sequentially such that each new tree corrects the errors of the previous one.

Bernoulli loss function was used since this is a classification problem. 5 cross-validations were conducted for each of the 100 cross-validation iterations.

AGE5YR and EMPLOY1 were identified as the most influential predictors, followed by SMOKER3, WTKG3, INCOME2, MENTHLTH, HTM4, CHECKUP1, GRENDA1 and MARITAL.

SCNTWRK1, PA1VIGM, PA1MIN, FRUTDA1, EDUCA, CHILDREN and BEANDAY were deemed by the model to have 0 influence.

### 4.4.3 Logistic Regression

The logistic regression model takes a linear combination of the 17 independent predictors to model the probability of having heart disease.

Backward stepwise logistic regression is used to optimize the model, where variables are removed from the original logistic regression model on a step-by-step basis to prevent overfitting, reducing multicollinearity between the variables used.

```

After stepwise regression, only **WTKG3**, **HTM4**, **AGEG5YR**, **EMPLOY1**, **GRENDAY**, **MARITAL**, **INCOME2**, **PA1VIGM**, **CHECKUP1**, **MENTHLTH** and **SMOKER3** remain.

**PA1MIN**, **BEANDAY**, **FRUTDA1**, **EDUCA**, **CHILDREN**, **SCNTWRK1** were deemed statistically insignificant, and hence excluded as predictors.

### 4.4.4 Neural Network

In the nnet package, the neural network architecture is fixed at a single hidden layer. The model was trained over a maximum of 200 iterations or until convergence.

Hyperparameter tuning is done for number of nodes within the single hidden layer, as well as for weight decay.

Through grid search, we found that the optimal size of 7 nodes and weight decay of 0.01 gives the best recall and accuracy.

#### 4.4.5 SVM

SVM draws hyperplanes in a N-dimensional space such that points on either side of the plane belongs to either one of the categories in a binary classification. The optimal hyperplane is one that maximizes its distance to points in either category

Using the example of AGE5YR and WTKG3 in a 2-dimensional plane, we see that the original inputs are not linearly separable by class.

The kernel trick is therefore used with the linear transformation sigmoid function (Meyer. D, 2022):

$$\tanh(\gamma u^T v + \text{coef0})$$

Original input data is mapped into a higher dimensional space such that the classes become more linearly separable (Wilimitis, 2018).

#### 4.5 Threshold Moving

After predictions were made, we sought to find the optimal threshold value under threshold moving to optimize the recall and accuracy of the models (Brownlee. J, 2020). Optimal threshold was found using a graphical approach, where optimal threshold is at maximum point of recall + accuracy as shown below.

SVM does not require a threshold for predictions.

	CART	GBM	Logistic Regression	Neural Network	SVM
Accuracy/ Recall trade-off					N/A
Optimal threshold	0.31	0.35	0.29	0.28	N/A

#### 4.6 Models Evaluation

	CART	GBM	Logistic Regression	Neural Network	SVM
Accuracy	66.69285	66.59859	<b>66.41005</b>	66.77141	67.24273
Recall	93.19136	95.62088	<b>96.19076</b>	95.35093	82.69346
Precision	62.14000	61.68731	<b>61.46033</b>	61.86028	64.64244
F1 Score	74.56204	74.99412	<b>75.00000</b>	72.03836	72.56218

SVM has the highest classification accuracy, but in medical related analytics, recall is the best metric because we want to capture as many positives as possible to minimize chances of missing positive cases, especially when misclassifying a high-risk patient as having no heart disease can have fatal consequences due to late detection.

$$\text{Recall} = \frac{\text{True Positives}}{\text{True Positives} + \text{False Negatives}}$$

Recall evaluates the ratio: Number of correctly identified heart disease cases / (Number of correctly identified heart disease cases + Number of misclassified cases for positive heart disease cases). Therefore, the final model that we will be using is backward stepwise logistic regression which has the highest recall, paired with a considerably high accuracy.

#### 4.7 Extracting Insights from models

We will be drawing insights based on our best performing logistic regression model in determining the variables' significance in relation to Y. The model showed high significance scores for various variables such as age, smoking behaviour and income. However, we will not be diving into factors like age and weight, as they are well-known to be influential in detecting heart diseases. Instead, we will be analysing uncommon factors, specifically marital status and income.

Multicollinearity does not exist among variables. Marital status and Income are independent predictors of heart disease.	Usage of chi-square test to prove that dependency exist between marital and heart disease as the p-value<0.001.	Usage of chi-square test to prove that dependency exist between income and heart disease as the p-value<0.001.																																																																																																																																																

## MARITAL

There is a higher percentage of those in “divorced”, “married” and “Separated” who contracted heart disease as compared to other groups. Thus, we would like to deep dive to find the underlying factors behind Marital Status that results in one getting heart disease.

By using CART to model Marital against the other variables, we found that age is the top factor in determining marital status.

Respondents under 40 tend to fall under “non-married” and “unmarried couple”, while the seniors are equally distributed across the different groups. However, the widowers have the largest percentage of seniors, and this could explain why they also have the higher proportion of heart disease. These charts imply that the age factor in Marital Status could be the underlying factor in prediction of heart disease. Thus, we cannot conclude with a high degree of certainty that marital status by itself is a strong determinant of heart disease.

AHA (2022) mentioned the relatedness of marital status to heart diseases could be due to a syndrome named “broken heart”. It can be caused by emotionally stressful events resulting from divorced or breakups. Hence, we choose to investigate the relation between mental health, marital status, and heart disease even though the variable has a low variable significance.

Indeed, we observe that as number of poor mental health days decreased, ratio of married to divorced and separated increases, showing a correlation between marriage and mental health where married couples generally have better mental health than divorcees and separated couples. Since we also observe that poor mental health is correlated with CHD risk, marriage could be a key contributing factor to CHD due to its influence on mental health.

## INCOME

As income increases, the chances of one contracting heart diseases falls. Therefore, we would like to investigate the underlying factors behind income group that results in one getting heart disease.

Once again, using CART to model income against other variables, education was found to be the most significant factor in determining income group

Income can be seen to be positively correlated to the level of education one attains. This trend is observed to be replicated among subset of groups of those with and without heart disease. Thus, this implies that if one has a higher level of education, they will have a higher income bracket which in turn, results in lower risk of getting heart disease.

Although deemed to be of low variable significance by the CART model, low income and work stress is researched to be the link between education and heart disease (ECS, 2019). Hence, there is a need for us to analyse and determine if mental health is the underlying factor, that is causing one to have heart disease.

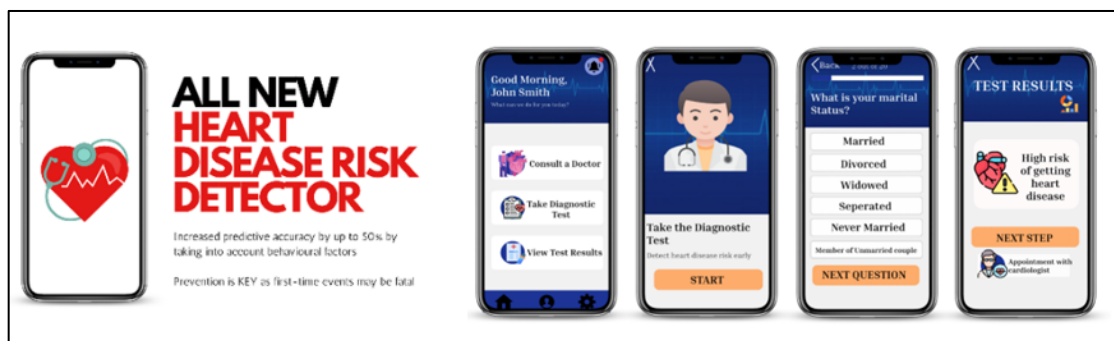

As income increases, the number of poor mental health days drop. The number of poor mental health days is also positively related to one getting heart disease as when the poor mental health days increase, the percentage of respondents getting heart disease is also higher. Hence, income is a good predictor of heart disease as it affects our mental health which in turn affects the risk of heart disease.

In summary, though marital status and income are assigned a high degree of variable importance by our primary logistic regression model, further analysis shows that their significance is strongly tied to mental health. In fact, the data shows that mental health is the key underlying consequence of marital status and income.

Mental health directly affects the risk of one getting heart disease. Many situations or factors contribute to our mental health, and one should not take lightly of it. Hence, these insights can be drawn on by doctors to explain to individuals the importance of placing emphasis on mental health and how it could have been a determining factor should they have been predicted to have a risk of heart disease.

## **5. Proposed Business Solution**

Our proposed business solution is to implement a model that helps the NHCS make well-informed and timely decisions. It will act as a tool to detect patients, that may be at a high risk of heart disease, at an early stage based on non-medical factors via an app. This tool will not replace the existing heart disease tests, like X-rays, CT scans, MRI scans, echocardiograms and electrocardiograms; instead, it would supplement the existing heart disease tests in place. (Mayo Clinic, 2022)

Heart Disease Risk-Detector App

### *Step 1: Patient provides non-medical data on a survey*

Patients can first provide non-medical data through a survey on the NHCS app. These non-medical factors will predominantly be those identified as important factors in the logistic regression model as stated above.

### *Step 2: Data is run through the regression model*

Subsequently, these data will be run through a pre-trained model to predict whether an individual is likely to get heart disease based on the data given by them prior to taking any heart disease tests.

### *Step 3: Results of the survey*

Based on the model, if the likelihood of the patient having heart disease is high, the survey will indicate that the patient is at a high risk of heart disease, along with the risk factors that contributed to this verdict. The patient can then consult a doctor for advice on the precautionary measures that must be taken to reduce the risk of heart disease. This doctor will obtain the details of the model prediction and data collected via the app. Moreover, the doctor may initiate a full body check up and take the necessary medical tests if the patient is in a very high risk of getting heart disease.

#### *Step 4: Patients taking the necessary steps*

Even if a patient is predicted to have a low likelihood of heart disease, they will be warned on the important behavioural factors identified by the model such as smoking that increases the risk of them developing heart disease in the future. Hence, the patients can take the necessary steps to help ensure that they mitigate any unhealthy habits that increase their risk in the future, such as reducing smoking.

#### 5.1 Value proposition over existing models

##### **Efficiency and Cost effectiveness**

Current early detection models rely on medical data such as blood pressure and cholesterol levels requiring individuals to undergo medical health screening. (Mercy Health, n.d.) This is time consuming and incurs cost for the individuals who, require early detection to seek timely treatment in case they, have a heart disease. Since our model that we have proposed allows individuals to do a self-check, through participating in a survey, individuals can gauge whether they are at a high or low risk of developing heart disease with the help of the survey results and be advised accordingly. This would be time saving and cost effective as it does not necessitate individuals to consult medical practitioners. Only when the result of the survey indicates that the individual has a high risk of heart disease, will they be advised to consult a doctor and seek advice on the precautionary measures that should be taken.

##### **Comprehensible and User-friendly**

Furthermore, current early detection models require the results to be analysed by medical professionals due to the extensive use of medical jargons in the results. This may not be comprehensible to individuals who lack sufficient knowledge in the medical domain. This is in contrast with the survey which allows individuals to easily understand on why they have a higher risk of heart disease and their behaviour that they must be mindful of if they want to reduce the risk of developing a heart disease.

##### **Alleviates stress on NHCS**

Currently, cardiac diagnostic tests are all done by medical professionals. Individuals may frequently visit the doctors as they are unable to self-gauge their risk of developing heart disease. Such unnecessary consultations are both time consuming and stressful for the doctors. With our solution, individuals will be able to conduct a self-assessment on the likelihood of them developing a heart disease through the survey. Thus, individuals would only have to consult the doctor if they are at a greater risk of heart disease, alleviating the stress on medical practitioners and NHCS.

#### **6. Conclusion**

In conclusion, the behavioural factors of individuals were used to analyse the likelihood of them developing a heart disease using 5 different models: CART, GBM, logistic regression, neural network and SVM. The logistic regression model, with the highest recall value, chosen as the best model will aid individuals to gauge whether they are at higher risk of heart disease through the survey. Our proposed solution is accessible to all individuals as it is comprehensible, user friendly and cost effective. Ultimately, individuals can make timely and well-informed decisions, consulting the doctor when necessary, alleviating the stress on NHCS.
